Vancomycin – continuous infusion Newborn Use Only

Draw up 2 mL (100 mg of vancomycin) of the above solution and add 18 mL glucose 5% or sodium chloride 0.9% to make a final volume of 20 mL with a final concentration of 5 mg/mL.

Using 1g VIAL

Add 20 mL of water for injection to the 1g vial to make a 50 mg/mL solution **FURTHER DILUTE**

Draw up 2 mL (100 mg of vancomycin) of the above solution and add 18 mL glucose 5% or sodium chloride 0.9% to make a final volume of 20 mL with a final concentration of 5 mg/mL

<u>Special circumstances</u> (10 mg/mL concentration- can only be given via central line)

For fluid restricted infants, vancomycin can be diluted to 10 mg/mL concentration

10 mg/mL concentration

Using 500mg VIAL

Add 10 mL of water for injection to the 500 mg vial to make a 50 mg/mL solution Further Dilute

Draw up 4 mL (200 mg of vancomycin) of the above solution and add 16 mL glucose 5% or sodium chloride 0.9% to make a final volume of 20 mL with a final concentration of 10 mg/mL.

Using 1g VIAL

Add 20 mL of water for injection to the 1g vial to make a 50 mg/mL solution **Further Dilute**

Draw up 4 mL (200 mg of vancomycin) of the above solution and add 16 mL glucose 5% or sodium chloride 0.9% to make a final volume of 20 mL with a final concentration of 10 mg/mL.

Vancomycin Baxter prefilled syringe is available as 10mg/mL concentration (100mg/10mL)

Administration

Loading dose: IV infusion over ONE hour.

Maintenance infusion: Continuous IV infusion. Change solution every 24 hours.

Monitoring

Renal function, full blood count, hearing function and serum vancomycin concentrations.

Target concentration 17-25 mg/L

Measure vancomycin concentration 24 hours after commencement of infusion AND 24 hours after each change of infusion rate.

Level 1 24 hours after commencement	Dose	Level 2	Timing of subsequent levels
17-25mg/L	Same	48 hours After first level	Every 3 days
<17mg/L	Increase	24 hours After dose adjustment	Every 3 days
>25mg/L	Decrease	24 hours After dose adjustment	Every 3 days

Repeat steady state level more frequently if

- 1. 10% change in body weight OR
- 2. 25% change in serum creatinine OR
- age-related dose adjustment OR
- 4. interruption in IV infusion OR
- 5. infant receives indomethacin.

If vancomycin level <17 or >25 mg/L: Adjust dose using below calculation:

Adjusted dose (mg/kg/hour) = last maintenance dose (mg/kg/hour) x (20mg/mL \div last vancomycin concentration)

For example:

1. Last dose was 2.1 mg/kg/hour and the last vancomycin concentration was 12 mg/L: Adjusted dose: 2.1 mg/kg/hour x (20 mg/L \div 12 mg/L) = 3.5 mg/kg/hour

Newborn Use Only

	2. Last dose was 2.1 mg/kg/hour and the last vancomycin concentration was 28 mg/L:		
	Adjusted dose: 2.1 mg/kg/hour x (20 mg/L \div 28 mg/L) = 1.5 mg/kg/hour		
	Adjustment to > 4.2 mg/kg/hour (100mg/kg/day) should be in consultation with pharmacist and consultant.		
Contraindications	Known hypersensitivity to vancomycin.		
Precautions	Use with caution in patients with renal impairment or those receiving other nephrotoxic, neurotoxic or ototoxic drugs.		
Drug Interactions	Neurotoxic and nephrotoxic drugs – concurrent use of these agents may contribute to the additive neurotoxic and nephrotoxic effects.		
	Diuretics – potent diuretics (e.g. furosemide [frusemide]) may add to the ototoxic effect.		
	Neuromuscular blocking agents (e.g. pancuronium, suxamethonium, vecuronium) – vancomycin may enhance neuromuscular blockade.		
	Vancomycin may be combined with an aminoglycoside, cephalosporin or rifampicin for synergistic activity.		
Adverse	Infusion related events: Rapid infusion may cause red man syndrome – a predominately histamine		
Reactions	mediated reaction with pruritus, tachycardia, hypotension and rash. It appears rapidly and usually dissipates in 30–60 minutes, but may persist for several hours. Increasing the infusion time usually eliminates the risk for subsequent doses.		
	Anaphylactic reactions may occur. Severe reactions may require treatment with adrenaline (epinephrine), corticosteroids and oxygen.		
	Phlebitis and tissue irritation with necrosis may occur, especially after extravasation. Intramuscular		
	injection is not recommended. Neurotoxicity, ototoxicity and nephrotoxicity – these are more pronounced with the addition of other		
	medications such as aminoglycosides or furosemide (frusemide).		
	Neutropenia and thrombocytopenia have been reported in adults; risk is increased with prolonged		
	therapy >1 week and they appear to be reversible when vancomycin is discontinued.		
Compatibility	Fluids: Glucose 5%, glucose 10%, sodium chloride 0.9%.		
	Y site: Amino acid solutions and fat emulsions, aciclovir, adrenaline (epinephrine) hydrochloride,		
	amifostine, amiodarone, anidulafungin, atracurium, caspofungin, cisatracurium, dobutamine,		
	dopamine, dexmedetomidine, esmolol, filgrastim, fluconazole, gentamicin, granisetron,		
	hydromorphone, insulin regular, labetalol, linezolid, magnesium sulfate, meropenem, midazolam, milrinone, morphine sulfate, mycophenolate mofetil, noradrenaline (norepinephrine), palonosetron,		
	pancuronium, pethidine, potassium chloride, remifentanil, tigecycline, vecuronium, zidovudine.		
Incompatibility	Y-site: Albumin, aminophylline, azathioprine, beta-lactam antibiotics (e.g. penicillins, cephalosporins),		
	bivalirudin, calcium folinate, chloramphenicol, daptomycin, foscarnet, furosemide (frusemide),		
•	ganciclovir, heparin sodium, indometacin, ketorolac, methylprednisolone sodium succinate, moxifloxacin, omeprazole, rocuronium, sodium bicarbonate, sodium valproate, streptokinase,		
	urokinase.		
Stability	Administer immediately, discard unused portion of reconstituted solution. Infusion solution is stable for 24 hours below 25°C.		
Storage	Store below 25°C. Protect from light.		
Special	If IV infusion is interrupted frequently or for longer periods of time, recommend changing over to		
Comments	intermittent regimen.		
	In severe sepsis, if the IV infusion is interrupted for short duration (e.g. up to 4 hours), consider giving		
Evidonos	the missed dose over an hour followed by the continuous infusion at the original rate. Pharmacokinetics/pharmacodynamics:		
Evidence	Vancomycin is water-soluble, has limited plasma protein binding and is mainly eliminated renally by		
	glomerular filtration, although its elimination is further modulated by renal tubular transport.[1]		
	Vancomycin is active against Gram-positive bacteria. <i>Staphylococcus epidermis</i> , including methicilling		
	resistant strains, is inhibited by vancomycin concentrations of 1–4 mg/mL; <i>Staphylococcus pyogenes</i> , <i>Streptococcus pneumoniae</i> , and <i>Streptococcus viridans</i> are susceptible to 2 mg/mL; <i>Bacillus</i> spp. are		
	inhibited by 2 mg/mL, Corynebacterium spp. by 0.04–3.1 mg/mL and Clostridium spp. by 0.39–6		
	mg/mL.[1]		
	Pharmacokinetic studies demonstrate variability that is only in part explained by weight, age or		
	creatinine.[1-4] These studies report that current dosage regimens typically achieve the rapeutic target		

Newborn Use Only

ranges for CoNS, MSSA and MRSA with MIC ≤1 microg/mL 50 to 60% of the time.[2] This variability necessitates the use of therapeutic drug monitoring (TDM) of trough concentrations to ensure effectiveness and avoid nephrotoxicity. In contrast, the quantification of peak concentrations provides no additional monitoring value.[1]

Because vancomycin activity is primarily time-dependent, the 24 hour area under the curve (AUC $_{0-24}$) divided by the MIC (AUC $_{0-24}$ /MIC) is a better predictor of efficacy. In adults with MIC values less than 1 mg/ml, trough concentrations >10 mg/mL result in AUC $_{0-24}$ /MIC values of >400.[1]

The elimination half life of vancomycin has been reported to range from 3.5 to 10 hours, decreasing with increasing gestation and postnatal age, and significantly longer in infants with a patent ductus arteriosus and with indomethacin treatment. [19]

In neonates, an RCT [5] compared intermittent intravenous (IV) dosing using the British National Formulary (BNF) dosage guidance [15 mg/kg/dose: <29 weeks 24-hourly; 29 to 35 weeks 12-hourly; 36 to 44 weeks 8-hourly; >44 weeks 6-hourly] versus continuous IV [loading dose of 15 mg/kg over 1 hour then continuous infusion: S creatinine <40 micromol/L, cGA \geq 40 = 50 mg/kg/day; S creatinine <40 micromol/L, cGA <40 = 40 mg/kg/day; S creatinine 40–60 micromol/L, cGA All = 30 mg/kg/day; S creatinine >60 micromol/L, cGA All = 20 mg/kg/day). The target trough concentration for intermittent IV dosing was 10 to 20 mg/L and steady state concentration for continuous IV 15 to 25 mg/L. Target concentrations at the first steady state concentration were higher for continuous IV compared with intermittent IV (45/53 (85%) vs 21/51 (41%); p <0.001)). Fewer dose adjustments and a lower total daily dose were required to achieve target concentrations with continuous IV compared to intermittent IV. No nephrotoxicity or red man syndrome occurred in either group. [LOE II]

There are few case reports of vancomycin cerebrospinal fluid concentrations with reported CSF penetration rates ranging from 7 to 42%.[1]

Efficacy: Clinical trials of vancomycin in newborn infants are largely underpowered so the relative efficacy of various antibiotic strategies is unclear. Concerns regarding the potential for antibiotic resistance developing result in recommendations to avoid the use of prophylactic antibiotics and reduce the duration of antibiotic therapy where possible.[6, 7]

Treatment of neonatal suspected sepsis: Two RCTs have compared the efficacy of vancomycin with other antibiotics in newborns with suspected sepsis.[8, 9] Deville et al 2003 [9] reported 63 neonates randomised 2:1 to linezolid (n = 43) or vancomycin (n = 20) with no significant difference in clinical cure rates (78% vs. 61%; P = 0.196). Ceriani Cernadas et al 2014 [8] reported 109 newborns randomised to cefazolin (52) or vancomycin (57) with no significant difference in rate of adequate outcome (no clinical signs, negative culture and normal laboratory test: cefazolin 92% versus vancomycin 86%) or mortality (cefazolin 7 (13.5%) versus vancomycin 11 (19.2%); p =0.45).

Gwee et al 2018 [5] compared intermittent intravenous (IV) dosing using the British Neonatal Formulary (BNF) dosage guidance versus continuous IV [loading dose of 15 mg/kg over 1 hour then continuous infusion). There was no difference in time to clearance of organism or mortality although this study was not powered to detect this.

Intraventricular antibiotics for bacterial meningitis in neonates: In a single trial that enrolled infants with Gram-negative meningitis and ventriculitis, the use of intraventricular gentamicin in addition to intravenous antibiotics resulted in a three-fold increased RR for mortality compared to standard treatment with intravenous antibiotics alone. No trial used intraventricular vancomycin. Based on this result, intraventricular antibiotics as tested in this trial should be avoided.[10] Arnell et al 2007 [11] reported 10 children (0 to 15 years) with intraventricular shunt infections initially treated with IV antibiotics for at least 3 days, but this treatment did not sterilise the CSF. After externalisation of the ventricular catheter, high-dose intraventricular treatment with daily instillations of vancomycin or gentamicin with trough concentrations held at high levels of 7 to 17 mg/L for both antibiotic agents resulted in quick sterilisation of the CSF, a low relapse rate and survival of all patients. The intraventricular vancomycin dose varied between 1 and 10 mg per day. [LOE IV]

Prevention of infection: Systematic review of 2 RCTs found prophylactic systemic antibiotics in neonates with a central venous catheter reduces the rate of proven or suspected septicaemia. However, there was no significant difference in mortality. There is a lack of data on long-term neurodevelopmental outcome and the potentially significant disadvantages of this approach such as the selection of resistant organisms. The routine use of prophylactic antibiotics in infants with central venous catheters in neonatal units cannot currently be recommended. [12] [LOE I GOR D] Three other

Newborn Use Only

RCTs have also reported similar effects of prophylactic vancomycin in infants with or with central lines.[13-15]

Newborn infants with necrotising enterocolitis: No trial included use of vancomycin.[16] **Prevention of necrotising enterocolitis:** Prophylactic oral vancomycin reduced the incidence of NEC in low birth weight infants. However, concerns about adverse outcomes persist, particularly related to the development of resistant bacteria. [17, 18] [LOE II GOR D]

Safety: Risk factors for developing nephrotoxicity are the following: Trough concentrations >10 mg/ml, concomitant treatment with aminoglycosides, piperacillin/tazobactam and/or prolonged therapy (>21 days).[1]

Other risk factors include high peak concentrations, high total dose, pre-existing renal failure and concurrent treatment with amphotericin and/or furosemide (frusemide). However, the role of these factors in the neonatal population is not well-established. Proper vancomycin TDM minimised both glomerular and tubular nephrotoxicity in two studies in children and neonates. In most cases, nephrotoxicity is reversible, even after high doses. In contrast, there is no proven association between TDM and ototoxicity prevention.[1]

Gwee et al 2018 [5] compared intermittent intravenous (IV) dosing using the British Neonatal Formulary (BNF) dosage guidance versus continuous IV [loading dose of 15 mg/kg over 1 hour then continuous infusion). No nephrotoxicity or red man syndrome occurred in either group.

Practice points

This is the first time the consensus group has introduced a continuous infusion regimen for vancomycin after publication of a RCT comparing continuous and intermittent regimen in newborn infants. [5]

A continuous regimen was reported to optimise achievement of steady state target concentrations with fewer dose adjustments and a lower total daily dose compared to an intermittent regimen. However, the participants' mean birth weight (2271 g), gestation at birth (34 weeks) and current weight (2549 g) were relatively higher than populations treated by many perinatal centres. However, there are practical issues in terms of intravenous access for continuous infusion in extremely premature infants. The consensus group considered that whilst continuous infusion has better pharmacokinetic efficacy the group is not able to recommend a preferred regimen.

In this revised version, monitoring section has been further improved: Vancomycin level is not a steady state at 24 hours. Half-life varies between 3.5 to 10 hours in newborns and is longer in renal impairment, PDA, indomethacin. Also, a level at 24 hours, then 3 days later as suggested in the previous version may miss some very high steady state levels which could occur after the 50 hour mark. Changes were made in this updated version to address this issue suggesting to measure at 24 hours, then 48 hours and then every 3 days.
